## ABSTRACT

We propose a survey experiment for a neutral hyperon beam, to measure production of  $\Lambda^0$ ,  $\bar{\Lambda}^0$ ,  $\Xi^0$ ,  $\bar{\Xi}^0$ ,  $K_1^0$  -  $K_2^0$  near zero mrad. by 200 GeV protons on complex nuclei. The detector will be sensitive to polarization of the hyperons. The same apparatus will then be used to search for  $\Xi^0 \rightarrow p\pi^-$  and to measure  $\Lambda^0$  and  $\bar{\Lambda}^0$  total and diffractive elastic cross sections in hydrogen.

\*Correspondent

## I. Neutral Hyperon Beam Survey

It has been known for some time that a practical neutral hyperon beam could be built at the National Accelerator Laboratory. Many features of this beam were considered in some detail during the 1969 summer study.<sup>1</sup> A charged particle spectrometer is described in this proposal which would be suitable for measurement of the relative fluxes in the neutral beam and for some early simple experiments. The experiments considered in detail are a search for the  $\Delta S=2$  weak transition  $\Xi^0 \rightarrow p\pi^-$  and a study of  $\Lambda^0$  cross sections in hydrogen in the 60 GeV - 130 GeV energy range. The apparatus required for these experiments is well within the limits of existing technology, and can be constructed by June, 1971. It is assumed that the short lived neutral beam will share a common facility with the short lived negative beam, and that the experimenters will be responsible for the compatibility. A high degree of collaboration between the laboratory and the neutral and negative beam groups is necessary to insure success of the program and to place minimum demands on the accelerator.

Production of  $\Lambda^0$  hyperons by 200 GeV protons in hydrogen has been calculated by Walker<sup>2</sup> using the formulas of Hagedorn and Ranft. Production of hyperons in complex nuclei has been considered by Margolis and Pilkuhn.<sup>3</sup>  $\Lambda^0$  hyperon production is predicted to reach approximately  $3\Lambda^0$  per sterad per GeV/c interacting proton at 0 mrad and 120 GeV/c. Since the decay length for 120 GeV/c  $\Lambda^0$  hyperons is 7.8 meters, the distance between the production target and the experimental area must be kept short, the order of 10 meters.

The main problem in the design of the short lived beam is the matching of this requirement to the shielding necessary for the operation of electronic detectors. Ten meters of iron would furnish a satisfactory hadronic shield, and the muons could be bent away magnetically, giving a muon free corridor for the apparatus. A curved channel could be cut in the shield to accommodate a negative hyperon beam. A 200 GeV proton beam in the intensity range  $10^8 - 10^{10}$ , suitable for production of useful hyperon fluxes, has been discussed for Experimental Area Two by J. Walker, R. Stefanski, and A. Roberts.<sup>4</sup> Figure 1 shows a proposed layout from the proton target to the experimental decay region.

Estimates of the expected neutral particle yields based on Walker's calculations are shown in Table I. These numbers indicate that a beam survey could be performed with as few as  $10^8$  interacting protons/pulse. Figure 2 shows the apparatus for the beam survey. The basic idea is to measure the invariant mass of two oppositely charged particles from two body decays of neutrals. The design mass resolution of the spectrometer will be  $\pm 1\%$ . The spectrometer magnet pole face should be about 30" wide with an 8" gap and a BL of 1800 kg-inches. Magnets with these characteristics are not uncommon at presently operating accelerators. For example an Argonne Labs BM-109 (24-8-72) could be used. The experimenters will be responsible for obtaining the magnet.

Great care must be taken in the construction of the spectrometer to keep the amount of material presented to the neutron beam to a minimum, and to keep the sensitivity of the apparatus to charged particle background as low as possible. No scintillators will be used in front of the magnet - the trigger will employ three "Charpak" counters. The

largest of these will be about 30 cm x 30 cm. Each counter will be  $2.5 \text{ mg/cm}^2$  thick, presenting about  $4 \times 10^{-5}$  of a neutron interaction length, or about  $10^4$  neutron counts/pulse in the third counter at full beam intensity. This should be a manageable counting rate. The large chambers behind the magnet will not be sensitive in the neutral beam region. The muon free "corridor" will cover all counters provided the spectrometer magnetic field and the magnetic field in the hadron shield are normal to each other.

Instantaneous data collection rates of the order of 500 per second during the beam spill will be buffer stored, and analyzed between accelerator pulses. When surveying the  $\Lambda^0$  and  $K_S^0$  components of the beam, a considerably reduced proton beam intensity could be used. For the  $\Xi^0$  studies, however, an incident flux of  $10^9$  protons on target would be convenient. At 1000 pulses/hour, our data capability would be roughly  $10^6$  triggers per day.

Table II shows the expected counting rates for a 10 meter decay length using the fluxes in Table I and the detector geometry of Fig. 2. The majority of decays will be approximately equal numbers of  $\Lambda^0 \rightarrow p\pi^-$  and  $K_S^0 \rightarrow \pi^+\pi^-$ . About 10% of these decays will fit either invariant mass because of the finite mass resolution of the system and the unknown beam momentum. This will present no problem for the yield measurements because the background will subtract easily from the peak, but the identification of a particular decay will be uncertain 10% of the time. This ambiguity can be resolved by the addition of a six meter long hydrogen gas cherenkov counter behind the magnet. This counter will serve to reject p's and  $\bar{p}$ 's with momentum below 80 GeV/c, and will

aid in measuring the yields of the other less copious neutral components of the beam. The reconstruction of the  $\Lambda^0$  events will allow a measurement of  $\alpha^{\Lambda^0 \bar{P}}$ , and hence the  $\Lambda^0$  polarization. To search for a non zero value of  $\bar{P}$ , data will be taken varying the incident proton beam angle, since it is expected that the polarization will have a very steep angular dependence. A downstream steering arrangement for the protons consisting of two main ring magnets would permit a study over a 10 mrad range.

The decay sequence  $\Xi^0 \rightarrow \Lambda^0 \pi^0$ ,  $\Lambda^0 \rightarrow p \pi^-$  will be detected by a coincidence between a  $\Lambda^0$  decay and a  $\gamma$  ray conversion from the  $\pi^0$ . A  $\gamma$  counter telescope will be placed behind the apparatus for this purpose. Aside from accidental coincidences the only background for this measurement will be  $\pi^0$  production by  $\Lambda^0$ 's in the beam, which should be a few percent of the expected  $\Xi^0$  yield. The flux of  $\bar{\Lambda}^0$ 's will be measured by using the gas cherenkov counter to veto  $\pi^-$  mesons, and reconstructing events assuming the charged particles to be  $(\pi^+ \bar{p})$ . If the gas counter is 98% efficient for  $\pi^-$ , then the  $K^0 \rightarrow \pi^+ \pi^-$  triggers will be a factor of 100 more numerous than the  $\bar{\Lambda}^0$  triggers, but only 10% of the  $K^0$ 's will reconstruct near the  $\bar{\Lambda}^0$  mass. The anti-hyperons will then be a 10% signal on a background which is slowly varying in invariant mass. In this case a statistically significant  $\bar{\Lambda}^0$  yield of several thousand events should be obtained in a day's run at  $10^8$  protons/pulse.

## II. Search for $\Xi^0 \rightarrow p\pi^-$ .

Weak decays in which  $\Delta S=2$  have not been observed at rates compatible with first order in the weak coupling constant  $G$ . The  $K_S^0 - K_L^0$  mass difference is generated by a  $\Delta S=2$  transition, but is consistent in magnitude with a second order weak interaction, since  $\delta m \sim r_s$ , which is proportional to  $G^2$ . However, terms in the weak Lagrangian which contribute to  $\delta m$  in first order must be even under charge conjugation, so it is possible that  $\Delta S=2$  transitions with branching ratios of  $10^{-3} - 10^{-4}$  exist which are odd under charge conjugation.<sup>5</sup> The observed CP violation could be one manifestation of such terms. There are not very many strange particle decays for which  $\Delta S=2$  channels are available. The present experimental limits on the transitions  $\Xi^- \rightarrow n\pi^-$  and  $\Xi^0 \rightarrow p\pi^-$  are each  $\lesssim 10^{-3}$ .<sup>6</sup> This experiment is designed to push the limit to  $\sim 10^{-6}$ .

Two modifications of the spectrometer system will be required to search for  $\Xi^0 \rightarrow p\pi^-$ . The decay distance will be shortened to six meters and the magnet gap shimmed to  $10''$  to increase the apertures because of the high transverse momentum of the decay. A ring scintillation counter will be inserted in front of the magnet to discriminate against protons from  $\Lambda^0 \rightarrow p\pi^-$  which will be closer to the neutral beam. About 12% of the  $\Xi^0 \rightarrow p\pi^-$  protons will be lost by this requirement, and 98% of the  $\Lambda^0$  decays will be rejected. Thus about  $3 \times 10^6$  triggers which will in fact be  $\Lambda^0 \rightarrow p\pi^-$  will be recorded and reconstructed in order to have "looked at"  $10^6 \Xi^0$ . This should take about 72 hours of running at  $10^9$  protons/pulse, and a data rate of 500 events/pulse.

### III. $\Lambda^0$ Cross Sections in Hydrogen.

The existing data on  $\Lambda p$  interactions have recently been compiled by the Particle Data Group.<sup>7</sup> The data extend up to 4 GeV/c, but are quite meager above .5 GeV/c. The total cross section in the GeV region is roughly 40 mb, half of which is elastic. The  $\Lambda p$  system appears to have no direct channel resonances, and is similar to  $pp$  except for the absence of the one pion exchange term in elastic scattering. It seems reasonable to use the  $pp$  system as a guide in estimating  $\Lambda p$  cross sections. Serpukhov data for  $pp$  scattering indicate a total cross section  $\sigma_T = 39$  millibarn and a diffraction elastic cross section of the form  $\frac{d\sigma}{dt} \propto e^{bt}$  where  $b \approx (7.0 + \ln S)\text{GeV}^{-2}$ .<sup>8</sup> The measurement of  $\Lambda p$  total and diffraction elastic cross sections in the region 60 GeV - 130 GeV would clearly be of considerable interest. Data for both cross sections can be taken simultaneously.

The experimental arrangement will be identical to that for the beam survey except for the insertion of a one meter long liquid hydrogen target in the upstream part of the ten meter decay path. To detect proton recoils from diffraction scattering a range telescope will surround the target in a  $2\pi$  azimuth configuration, and will be sensitive to protons with energies between about 40 MeV and 250 MeV. A 40 MeV proton corresponds to a momentum transfer  $t = 2MT = .08 (\text{GeV})^2$ , and a scattering angle  $\theta = 3$  mrad for a 100 GeV  $\Lambda^0$ , which will be approximately the  $e^{-1}$  point in the diffraction cross section if the parameter  $b \sim 10 (\text{GeV})^{-2}$ . Smaller momentum transfers will be difficult to detect by a coincidence method, so an extrapolation technique will be required to obtain  $\frac{d\sigma}{dt} (t=0)$ . The total cross section will be measured by a

transmission method. The inherent width of the beam defined by the collimator will be 0.6 mrad fwhm with perhaps wings from collimator halo and scattering in the empty target. With the target full the diffraction scattering will contribute to the wings, as will  $\Lambda^0$  production by the  $K_L^0$  and  $n$  components of the beam. Since these effects will create  $\Lambda^0$ 's appreciably outside of the inherent beam width, the subtraction of the "background" from the undeflected hyperon beam should be possible.

While the neutrons should present no problem through production of  $\Lambda^0$ 's, they will create an intense charged particle background which will limit the useable flux in the neutral beam. The ratio in Table I for  $n/\Lambda^0 \sim 200$ ; assuming every neutron produces one charged particle in one meter of hydrogen, a maximum neutron intensity of  $\sim 5 \times 10^4$  per pulse, or 200  $\Lambda^0$ / pulse will be required to keep the accidentals rates manageable. If  $\sigma_{\text{tot}} \sim 40$  mb, 13% of the  $\Lambda^0$ 's will interact in one meter of hydrogen, so the statistical error in the difference measurement will be  $\sim \frac{11}{\sqrt{N}}$  where  $N$  is the flux of unscattered hyperons. Thus 200  $\Lambda^0$ /pulse will give  $2 \times 10^6$   $\Lambda^0$  per day, or a statistical error of a few percent in  $\sigma_{\text{tot}}$  in the 80 GeV to 120 GeV region where most of the detected  $\Lambda^0$  flux will be concentrated. Increasing the  $\Lambda^0$  production angle at the proton target from near 0 to 5 mrad or even 10 mrad will decrease the  $n/\Lambda^0$  ratio at production, but this improvement will be lost in the 3 meter flight path through the shield because the  $\Lambda^0$  momentum spectrum shifts to lower momenta as the production angle is increased.

The measurement of  $\bar{\Lambda}^0 p$  total cross sections may also be feasible. The use of a 10 mrad production angle for the neutral beam would be advantageous in this case, because the antiparticle momentum spectrum

should not shift downward sharply compared to 0 mrad. Thus the  $n/\bar{\Lambda}^0$  ratio should be  $\sim 2 \times 10^4$  at 10 mrad, rather than  $2 \times 10^6$  quoted in Table I. Using the accidentals limits quoted above, a maximum beam of a few  $\bar{\Lambda}^0$  per pulse should be possible, requiring the order of  $10^9$  protons/pulse on target. Since the cross sections for  $\bar{\Lambda}^0 p$  will be larger than the  $\Lambda^0 p$  cross sections, measurements of  $\sigma(\bar{\Lambda} p)$  to 10% could be obtained in the order of one week of running.

#### IV. Summary - Requirements for the Experiment.

The following requirements will be placed on the accelerator facilities:

- 1.) A proton beam near 200 GeV with a slow spill and an intensity variable between  $10^8$  and  $10^9$  protons/pulse. Steering magnets to vary the incident proton angle at the hyperon production target over the range 0-10 mrad would be advantageous. This requires two main-ring magnets.
- 2.) A neutral channel of approximately one microsterradian solid angle in a magnetized hadron shield 10 meters long.
- 3.) Floor area for the apparatus roughly 35 meters long by 3 meters wide by 3 meters high.
- 4.) A 1 meter cylindrical hydrogen target 2.5 cm. in diameter.
- 5.) Total number of beam protons interacting in the target:
  - a.)  $6 \times 10^{12}$  protons at  $10^8$  /pulse for tuning and beam survey (3 days);
  - b.)  $10^{13}$  protons at  $3 \times 10^8$  /pulse for the  $\Xi^0 \rightarrow p\pi^-$  search (3 days);
  - c.)  $7 \times 10^{12}$  protons at  $5 \times 10^7$  /pulse for the  $\Lambda^0 p$  and  $\bar{\Lambda}^0 p$  scattering measurements (1 week).

The following apparatus will be furnished by the experimenters:

- 1.) Chambers, counters and associated electronics.
- 2.) High speed buffer storage register.
- 3.) Spectrometer magnet with a gap approximately 30" wide and 8" high, BL = 1300 kg. - inches, to be borrowed or built on a cost shared basis. The total cost should be about \$80,000.
- 4.) On line computer in the ASI 60-40 class (24 bit words, 32k memory). The computer facility will be shared with the negative hyperon experiment.

TABLE I

Neutral particle fluxes estimated using Walker's<sup>2</sup> yield curves. A solid angle of  $10^{-6}$  sterad at 0 mrad and a flight path of 8 meters were assumed. All fluxes are per  $10^{10}$  interacting protons.

<u>Particle</u>	<u>Flux</u>	<u>Most Probable Momentum</u>	
n	$10^8$	180	Slowly varying momentum Spectrum 100-200 GeV/c
$\bar{n}$	$10^5$	40	Anti-particle momentum Spectrum falls off sharply with increasing momentum
$\Lambda^0$	$5 \times 10^5$	120	
$\bar{\Lambda}^0$	$50 \text{ ?}^a$	40	
$\Xi^0$	$5 \times 10^3 \text{ ?}^b$	120?	Same momentum spectrum Assumed for $\Xi^0$ and $\Lambda^0$
$\Xi^0$	.5	40	
$K_L$	$1.35 \times 10^6$	60	} Vacuum interference Significant at ~20 GeV/c
$K_S$	$.15 \times 10^6$	80	

a) Antiparticle/particle ratio assumed to be  $10^{-3}$ . The extra factor of .1 comes from the decay of the  $\bar{\Lambda}^0$ 's which have an average momentum 1/3 that of the  $\Lambda^0$ 's.

b) The  $\Xi$  flux is rather arbitrarily taken to be 1% of the  $\Lambda^0$  flux.

TABLE II

Neutral particles detected in a 10 meter decay length. These numbers were obtained from the fluxes and momentum spectra in Table I, combined with the appropriate lifetimes, branching ratios, and detection efficiencies. All yields are for  $10^{10}$  interacting protons.

<u>PARTICLE</u>	<u>FLUX 8M FROM TGT</u>	<u>YIELD FROM 8 to 18 M</u>
$\Lambda^0$	$5 \times 10^5$	$2.6 \times 10^5$
$\bar{\Lambda}^0$	50	26
$\Xi^0$	$5 \times 10^3$	$1.3 \times 10^3$ <sup>a</sup>
$\bar{\Xi}^0$	.5	.1
$K_S^0$	$1.5 \times 10^5$	$1.0 \times 10^5$
$K_L^0$	$1.35 \times 10^6$	$2 \times 10^3$ <sup>b</sup>

a.) For illustration, the efficiency of .26 for  $\Xi^0$  comes from .33 for the chain  $\Xi^0 \rightarrow \Lambda^0 \rightarrow p\pi^-$  to be detected in 10 meters, and .8 for detecting a  $\pi^0$   $\gamma$  ray behind the apparatus.

b.) This number includes leptonic and  $\tau$ 's which count but do not have unique invariant mass. For  $K_L^0 \rightarrow \pi^+\pi^-$ , the expected yield is  $\sim 10$ .

## FIGURE CAPTIONS

- 1.) Possible shield and collimator configuration for the short lived beams. The letters refer to the following: A) incident proton beam in the intensity range  $10^8$  -  $10^9$  with variable angle of incidence over 0 - 10 mrad; B) one interaction length Cu target; C) heavymet or other high density shield near the target with a channel in the forward direction; D) one microsterad channel in the iron shield, 8 meters long; and E) magnetized iron shield. The heavymet high density shield is solid for about 1/2 interaction length in the direction of the neutral beam to eliminate the  $\gamma$  ray component.
- 2.) Proposed experimental arrangement for the beam survey. A vacuum pipe will be placed along the 10 meter decay length during the survey to minimize gas interactions. P1, P2, P3 are proportional counters of the Charpak type. M is the analyzing magnet. S1, S2, S3 are magnetostrictive readout wire chambers. C is a 6 meter long hydrogen gas Cherevkov counter split into two separate compartments for positively and negatively charged particles. P1 and H2 are scintillation counter hodoscopes, and H3 is a lead and lucite hodoscope for  $\gamma$  ray conversion. For the cross section studies a 1 meter long liquid hydrogen target will be inserted at  $LP_2$ .
